What is Dark Matter, and where to find them?

↳ What is Dark Matter, and where to find them?

2025-05-09

I work on the dark matter problem. I approach this problem from two directions, primordial black holes and galaxy sub-halos. For primordial black holes, I investigate main sequence star – black hole binaries. For sub-halos, I turn to galaxy-galaxy scale strong lenses.

- Unless the limits from evaporation and CMB limits from Planck are relaxed the scenario of the dark matter fully composed of PBH is ruled out [11].
- The effect of various PBH fractions on the total power spectrum of the DM density field is shown in figure below compared to standard Λ CDM model [27].

Adapted from Zhang, Bromm, and Liu [27] (Figure 1).

PBHs can provide a compelling explanation for the dark matter problem. In figure $m_{\text{PBH}} = 33 \text{ Msun}$, they choose this mass because it is the location of the (secondary) Gaussian peak in the best-fit Power-Law + Peak model of the mass distribution of BHs detected in GW observations of binary BH mergers by the LIGO-Virgo-KAGRA Scientific Collaboration. Varying m_{PBH} by a factor of a few does not change our conclusions

- ⇒ However, the degeneracy on the semimajor axis for these three subpopulations of the BH-MS binaries might break.

I propose to use semimajor axis distributions to resolve the origins of the binary systems that will be detected by microlensing events.

- So let's assume we observed such a binary system, we need to be able to distinguish these three scenarios to tell if the black hole in the binary is a PBH or not
- To do that, we may look at the distributions over semimajor axis for each population. If they have occurrence rates that peak at distinct semimajor axis values we might have a clue about their origins.

Prospects of Finding Detached Black Hole–Star Binaries with *TESS*

Kento Masuda¹ and Kenta Hotokezaka¹

Department of Astrophysical Sciences, Princeton University, Princeton, NJ 08544, USA; kmasuda@astro.princeton.edu

Received 2018 August 31; revised 2019 August 1; accepted 2019 August 8; published 2019 October 1

Abstract

We discuss prospects of identifying and characterizing black hole (BH) companions to normal stars on tight but detached orbits, using photometric data from the *Transiting Exoplanet Survey Satellite* (*TESS*). We focus on the following two periodic signals from the visible stellar component: (i) in-eclipse brightening of the star due to gravitational microlensing by the BH (self-lensing), and (ii) a combination of ellipsoidal variations due to tidal distortion of the star and relativistic beaming due to its orbital motion (phase-curve variation). We evaluate the detectability of each signal in the light curves of stars in the *TESS* input catalog, based on a pre-launch noise model of *TESS* photometry as well as the actual light curves of spotted stars from the prime *Kepler* mission to gauge the potential impact of stellar activity arising from the tidally spun-up stellar components. We estimate that the self-lensing and phase-curve signals from BH companions, if they exist, will be detectable in the light curves of effectively $\mathcal{O}(10^5)$ and $\mathcal{O}(10^6)$ low-mass stars, respectively, taking into account orbital inclination dependence of the signals. These numbers could be large enough to actually detect signals from BHs: simple population models predict some 10 and 100 detectable BHs among these “searchable” stars; although, the latter may be associated with a comparable number of false positives due to stellar variabilities, and additional vetting with radial velocity measurements would be essential. Thus, the *TESS* data could serve as a resource to study nearby BHs with stellar companions on shorter-period orbits than will potentially be probed with *Gaia*.

Key words: stars: black holes – stars: neutron – techniques: photometric – white dwarfs

⇒ In Masuda & Hotokezaka [15], the 'searchability' constraint includes various criteria such as recovery rate as a function of the signal-to-noise ratio C_{rec} and the eclipse probability R_{star}/a

$$N_{eff} = \frac{R_{star}}{a} C_{rec} \left(\sqrt{n} \frac{s_{self-lensing}}{\sigma_{30min}} \right) \quad (1)$$

while the values compared above only include the criteria of edge-on configuration for the binaries, given by $\cos_i \leq \cos(89.9) \approx \cos(\pi/2) = 0$

$$\cos_i \leq \cos(89.9) \approx \cos(\pi/2) = 0 \quad (2)$$

which yields a *searchability index* of ≈ 0.0011 .

2025-05-09

→ In Masuda & Hotokezaka [15], the 'searchability' constraint includes various criteria such as recovery rate as a function of the signal-to-noise ratio C_{rec} and the eclipse probability R_{star}/a

$$N_{eff} = \frac{R_{star}}{a} C_{rec} \left(\sqrt{n} \frac{s_{self-lensing}}{\sigma_{30min}} \right) \quad (1)$$

while the values compared above only include the criteria of edge-on configuration for the binaries, given by $\cos_i \leq \cos(89.9) \approx \cos(\pi/2) = 0$

$$\cos_i \leq \cos(89.9) \approx \cos(\pi/2) = 0 \quad (2)$$

which yields a *searchability index* of ≈ 0.0011 .

The main cause of the current residual values is the duality of the searchability criteria. I will evaluate the additional constraints and minimize the residuals to confirm that the occurrence rates from COMPAS simulation are reasonable and in line with the occurrence rates expected from TESS by Masuda and Hotokezaka [14]. Then, in the first part of this task, I will search for microlensing events in TESS data with predicted mass and semimajor axis parameters to compare with the COMPAS results. A discrepancy between the predicted and observed populations where observed abundance is higher or a discrepancy of the peak semimajor axis might indicate BH-MS systems formed by capture.

Star-Bound Primordial Black Holes as a Probe of Dark Matter

Preliminary Results

Capture cross section from gravitational radiation

2025-05-09

Power radiated is given by the quadruple formula [7]

$$P = -\frac{G}{5c^2} \left\langle \frac{d^3 J_{ij}}{dt^3} \frac{d^3 J^{ij}}{dt^3} \right\rangle \quad (3)$$

→ J_{ij} : reduced quad. moment ⇒ $J_{ij} = I_{ij} - \frac{1}{3}\delta_{ij}\delta^{kl}I_{kl}$

→ I_{ij} : quad. moment tensor ⇒ $I(t)_{ij} = \int y^i y^j T^{00}(t, y) d^3 y$

$$\Delta E_{GW} = \int_{-\infty}^{\infty} P(t) dt = \frac{8}{15} \frac{G^{7/2} M^{1/2} m_1^2 m_2^2}{c^5 r_{min}^{7/2}} g(e) \quad (4)$$

$$g(e) = \frac{[24 \cos^{-1}(-\frac{1}{e})(1 + \frac{73}{24}e^2 + \frac{37}{96}e^4) + (e^2 - 1)^{1/2}(\frac{301}{6} + \frac{673}{12}e^2)]}{(1+e)^{7/2}}$$

From here, we turn to binaries formed by capture. First capture mechanism we will investigate is the capture by energy loss due to gravitational wave emission. GW solutions come from the linearized field equations where space-time is considered to have the Minkowski metric, and Einstein's equation coupled to matter, where the strain tensor represents the gravitational waves [7].

In this solution, the power radiated is given by the quadruple formula. ($I(t)_{ij}$ depends on the trajectories of the bodies in the encounter system). Then, the gravitational energy loss can be computed by [23] where *enhancement factor*: $g(e)$ for $e \geq 1$

$$r_{min} = \frac{GM}{v_\infty^2}(e - 1) = \frac{GM_S}{v_\infty^2} \left(\sqrt{1 + \frac{b^2 v_\infty^4}{G^2 M_S^2}} - 1 \right) \quad (5)$$

Setting $r_{min} = R_S$ for R_S :radius of the star

$$b_{min} = \sqrt{R_S^2 + \frac{2GM_S R_S}{v_\infty^2}} \quad (6)$$

$b_{max} \rightarrow$ solved numerically.

\Rightarrow Capture condition:

$$\Delta E_{GW} > \frac{1}{2} M_{PBH} v_\infty^2$$

$$r_{min} = \frac{GM}{v_\infty^2}(e - 1) = \frac{GM_S}{v_\infty^2} \left(\sqrt{1 + \frac{b^2 v_\infty^4}{G^2 M_S^2}} - 1 \right) \quad (5)$$

Setting $r_{min} = R_S$ for R_S :radius of the star

$$b_{min} = \sqrt{R_S^2 + \frac{2GM_S R_S}{v_\infty^2}} \quad (6)$$

$b_{max} \rightarrow$ solved numerically.

\Rightarrow Capture condition:

$$\Delta E_{GW} > \frac{1}{2} M_{PBH} v_\infty^2$$

To avoid collisions, we set $r_{min} = R_S$ where R_S is the radius of the star, [12]. b_{max} requires numerical calculations. We start by imposing the capture condition $\Delta E_{GW} > \frac{1}{2} M_{PBH} v_\infty^2$ that indicates the energy loss due to GW is enough to turn PBH's energy negative so that the encounter yields an elliptic trajectory ($e < 1$) in which PBH becomes bound to the star. For $e < 1$, the encounter is a hyperbolic trajectory, PBH remains unbound with positive energy, and escapes after the event. $e = 1$ gives a parabolic trajectory with zero energy, and $e < 1$ results in an elliptic trajectory with negative energy, PBH becomes bound to the star.

Capture crosssection by gravitational wave emission σ_{cap}^{GW}
[12] $\sigma_{cap}^{GW} = \pi(b_{max} - b_{min})^2 \Theta(b_{max} - b_{min})$ hence the capture rate

$$R_{cap}^{GW} = n_\infty \langle \sigma_{cap} v_\infty \rangle = n_\infty \int dv f_\infty(v) \sigma_{cap} v \quad (8)$$

where $f_\infty(v) \propto v^2 \exp\left(-\frac{v^2}{v_0^2}\right) \Theta(v_{esc} - v)$ we take $v_0 = 220\text{km/s}$ & $v_{esc} = 550\text{km/s}$

n_∞ is the number density of objects far from the system and angle brackets denote the average over velocities.

$f(v)$ This probability density is an approximate description of the equilibrium distribution of DM particles — in our case, PBHs — throughout the halo. Near a point mass like a star, the velocity distribution is modified by the local gravitational potential. Thus, $f(v)$ should be treated as the distribution of particles far from the stellar system.

σ_{cap}^{GW} for GRO J0422 + 32 (V518 Per). Red dashes denote the mass of the black hole used in the calculations, $M_{BH} = 6.5M_{\odot}$. Grey dashes show the semi-major axis values right after the capture.

Here you can see an example calculation following this procedure. This is the Smallest BH detected so far. Its companion is a main sequence star
The system has a 5h period, which approximately makes $T = 5h 4m 35s \approx a = 0.01326$ AU. We see that GW capture semimajor axis values are much higher than this, if it were formed by capture.

For fixed v_∞ ,

$$\tilde{N} = \widetilde{R_{cap}} / \widetilde{R_{ej}} \quad (10)$$

$$\langle \tilde{N} \rangle = \int \frac{\widetilde{R_{cap}}}{\widetilde{R_{ej}}} = n_\infty \int d\mathbf{v}_\infty f(v_\infty) \frac{\widetilde{\sigma}_{cap}(v_\infty) v_1(v_\infty)}{\widetilde{R_{ej}}(v_\infty)} \quad (11)$$

where $\widetilde{\sigma}_{cap}$ is integrated over da & de .
Also,

$$\widetilde{R_{ej}} \propto \eta(a, e), \quad \xi(a), \quad \kappa_\pm(\eta, \xi) \quad (12)$$

To obtain a closed-form estimate, we can use mean values instead of integrating over da & de

$$a \rightarrow \bar{a}, \quad e \rightarrow \bar{e}(2) = \frac{1}{2}(1 + e_{min}) \quad (13)$$

We're essentially interested in the expected number of captured PBHs by the star.

If the captured objects do not interact among themselves, then the capture rate is independent of the number of captured objects.

We can thus estimate N for fixed v_{inf} and can average over the population.

Side Quest

From evolution simulation and the capture calculations we roughly see that binaries evolved together undergoing mass transfer events have $a < 1$ AU while those formed by capture have $a > 1$ AU.

Considering what we observe so far, the idea of inspecting black hole origins using the distributions over semimajor axis seems to make sense.

Side Quest

- 1 v_{inf} of stellar BHs kicked out of their binaries and free floating PBH might be different, directly affecting the capture rates with any methods
- 2 For now, capture rate calculations from GW can be used to test the possibility of forming by capture of an observed system. In my future work, I will eventually derive the capture rates.

Side Quest

2025-05-09

- Evaluation $\langle \bar{N} \rangle$ from the three-body capture and ejection crosssections calculated so far
- More simulations on a larger variety of initial parameters, better analysis of the relation between the parameters that enable capture events and their occurrence in nature.
- Create a simulation and analysis pipeline development towards searching microlensing signals in the upcoming Roman data.

I also need to consider the three-body capture and ejection, and apply both capture mechanisms for a large number of systems. Then I will investigate the TESS data for microlensing events that might belong to a BH-MS system, and start preparing a pipeline to work with upcoming Roman data.

Side Quest

⇒ For Λ CDM, various studies by Navarro et al. utilizing N-body simulations led to a 'universal' density profile, known as **The Navarro–Frenk–White (NFW) profile** :

$$\frac{\rho(r)}{\rho_{crit}} = \frac{\delta_c}{r_s(1 + \frac{r}{r_s})^2} \quad (14)$$

where r_s is the characteristic radius of the halo (scale radius), δ_c is the characteristic density and $\rho_{crit} = 3H^2/8\pi G$ is the critical density [18, 17].

→ For Λ CDM, various studies by Navarro et al. utilizing N-body simulations led to a 'universal' density profile, known as **The Navarro–Frenk–White (NFW) profile** :

$$\frac{\rho(r)}{\rho_{crit}} = \frac{\delta_c}{r_s(1 + \frac{r}{r_s})^2} \quad (14)$$

where r_s is the characteristic radius of the halo (scale radius), δ_c is the characteristic density and $\rho_{crit} = 3H^2/8\pi G$ is the critical density [18, 17].

In literature, for the galaxy density profiles, the simulations indicate Navarro–Frenk–White model...

Side Quest

⇒ The rotation curves inferred from the observations of the dark matter-dominated Low-Surface-Brightness(LSB) galaxies sides with the 'pseudo-isothermal' (PI) sphere profile,

$$\rho_{PI} = \frac{\rho_0}{1 + (\frac{r}{R_C})^2} \quad (15)$$

where R_C is the core radius of the halo [18, 2].

= The rotation curves inferred from the observations of the dark matter-dominated Low-Surface-Brightness(LSB) galaxies sides with the 'pseudo-isothermal' (PI) sphere profile,
$$\rho_{PI} = \frac{\rho_0}{1 + (\frac{r}{R_C})^2} \quad (15)$$

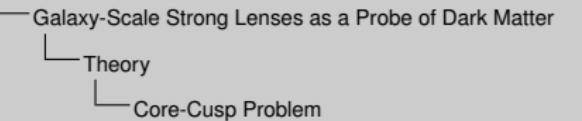

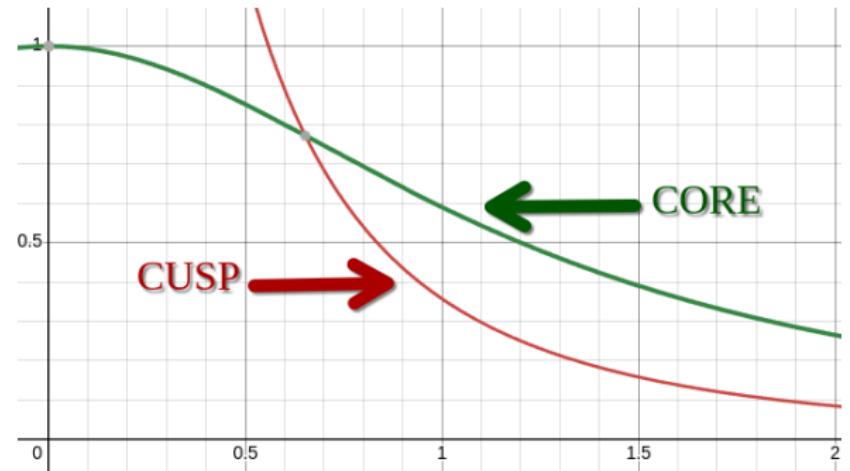

where R_C is the core radius of the halo [18, 2].

While the observational data results in pseudo-isothermal' (PI) sphere profile.

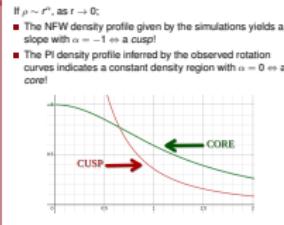

Core-Cusp Problem

If $\rho \sim r^\alpha$, as $r \rightarrow 0$:

- The NFW density profile given by the simulations yields a slope with $\alpha = -1 \Leftrightarrow$ a *cusp*!
- The PI density profile inferred by the observed rotation curves indicates a constant density region with $\alpha = 0 \Leftrightarrow$ a *core*!

2025-05-09

So, the simulations suggests a cusp towards the galactic center, but observations show that the density stays constant. This is known as the core-cusp problem.

Side Quest

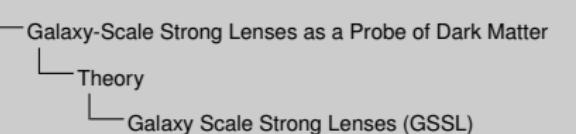

→ *The small scale crisis in cosmology*

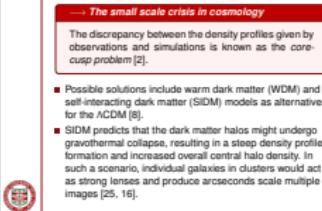

The discrepancy between the density profiles given by observations and simulations is known as the *core-cusp problem* [2].

- Possible solutions include warm dark matter (WDM) and self-interacting dark matter (SIDM) models as alternatives for the Λ CDM [8].
- SIDM predicts that the dark matter halos might undergo gravothermal collapse, resulting in a steep density profile formation and increased overall central halo density. In such a scenario, individual galaxies in clusters would act as strong lenses and produce arcseconds scale multiple images [25, 16].

Alternative Theories of Dark Matter in the Light of Gravitational Lensing

2025-05-09

Self interacting dark matter might be a solution. In this scenario, galaxies with high density central halos could act as strong lenses.

- Primordial black holes (PBHs) are hypothetical objects that could have formed as highly over-dense regions collapse gravitationally in the early universe, by mechanisms such as adiabatic quantum fluctuations appearing during inflation [3, 10], collapse from density fluctuations and various collapse scenarios including domain walls, cosmic loops, bubble collisions [4].
- They have non-stellar origins [21].
- First suggested in [26], and also independently in [9], they have been a source of attention for almost 50 years due to their extraordinary properties such as constituting primordial non-baryonic matter from the radiation-dominated era [24, 5]

other cosmological conundra. In particular, many authors have discussed the possibility that PBHs could provide the dark matter [22, 562]. In this context, Fig. 10 might suggest that the asteroid range $10^{17} \text{ g} < M < 10^{23} \text{ g}$ between the EGB and HSC microlensing limits is most plausible. However, the intermediate range $10 M_{\odot} < M < 10^2 M_{\odot}$ between the LMC microlensing and wide binary limits is still favored by some theorists, even though this appears to violate other constraints, because PBHs may naturally form in this range. In principle, Fig. 10 suggests that a lot of dark matter could reside in “stupendously large black holes” in the range $10^{14} M_{\odot} < M < 10^{17} M_{\odot}$, although the lack of constraints there probably just reflects the fact that little attention has been paid to this possibility and obviously such SLABs could not provide dark matter inside galactic halos [426]. A final possibility is the Planck-mass relics of Hawking evaporation in the range around $M \sim 10^{-5} \text{ g}$, although this is probably untestable unless the relics are electrically charged [138].

Abstract

We review the formation and evaporation of primordial black holes (PBHs) and their possible contribution to dark matter. Various constraints suggest they could only provide most of it in the mass windows $10^{17} - 10^{23}$ g or $10 - 10^2 M_\odot$, with the last possibility perhaps being suggested by the LIGO/Virgo observations. However, PBHs could have important consequences even if they have a low cosmological density. Sufficiently large ones might generate cosmic structures and provide seeds for the supermassive black holes in galactic nuclei. Planck-mass relics of PBH evaporation or stupendously large black holes bigger than $10^{12} M_\odot$ could also be an interesting dark component.

-lensing in binary systems occurs when the compact object gravitationally deflects the light from the star as it transits

Maeder [13].

So their relatively higher brightness magnitudes is why we study MS stars as PBH companions in this work.

I use the rapid stellar and binary population synthesis tool COMPAS to simulate parameter distribution and occurrence of BH-MS systems in nature [20].

work focuses on particular input parameters such as the initial masses of the primary and secondary stars, the initial semi-major axis, and the initial mass function as a parameter for the population characteristics. All the remaining parameters required for the simulation to run are taken as the default values. Both primary and secondary stars ('Primary' refers to the companion with the higher mass in the binary while 'secondary' is the lower mass companion) in every binary start their evolution as MS stars with masses sampled from Kroupa Initial Mass Function. Characteristic events of the stellar evolution such as common envelope (CE) formation and mass transfer (MT) events can be tracked for the simulated binaries during their lifetime. Preliminary simulations show that about 58% of the binaries undergo MT events that have a substantial impact on the binary system not only by altering the mass distribution but also by initiating the stellar-type transformations of the companions. Binaries may have multiple MT events that enable their evolution into any stellar type on Table 2 in [20]. Depending on the initial parameters and MT events, binaries can undergo supernovae, form double compact objects (DCO), unbound binaries, or mergers.

We take the mean occurrence plots on Masuda & Hotokezaka's work [14] as a basis to reproduce them using COMPAS results.

Prospects of Finding Detached Black Hole–Star Binaries with *TESS*

Kento Masuda¹ and Kenta Hotokezaka¹

Department of Astrophysical Sciences, Princeton University, Princeton, NJ 08544, USA; kmasuda@astro.princeton.edu

Received 2018 August 31; revised 2019 August 1; accepted 2019 August 8; published 2019 October 1

Abstract

We discuss prospects of identifying and characterizing black hole (BH) companions to normal stars on tight but detached orbits, using photometric data from the *Transiting Exoplanet Survey Satellite* (*TESS*). We focus on the following two periodic signals from the visible stellar component: (i) in-eclipse brightening of the star due to gravitational microlensing by the BH (self-lensing), and (ii) a combination of ellipsoidal variations due to tidal distortion of the star and relativistic beaming due to its orbital motion (phase-curve variation). We evaluate the detectability of each signal in the light curves of stars in the *TESS* input catalog, based on a pre-launch noise model of *TESS* photometry as well as the actual light curves of spotted stars from the prime *Kepler* mission to gauge the potential impact of stellar activity arising from the tidally spun-up stellar components. We estimate that the self-lensing and phase-curve signals from BH companions, if they exist, will be detectable in the light curves of effectively $\mathcal{O}(10^5)$ and $\mathcal{O}(10^6)$ low-mass stars, respectively, taking into account orbital inclination dependence of the signals. These numbers could be large enough to actually detect signals from BHs: simple population models predict some 10 and 100 detectable BHs among these “searchable” stars; although, the latter may be associated with a comparable number of false positives due to stellar variabilities, and additional vetting with radial velocity measurements would be essential. Thus, the *TESS* data could serve as a resource to study nearby BHs with stellar companions on shorter-period orbits than will potentially be probed with *Gaia*.

⇒ In Masuda & Hotokezaka [15], the 'searchability' constraint includes various criteria such as recovery rate as a function of the signal-to-noise ratio C_{rec} and the eclipse probability R_{star}/a

$$N_{eff} = \frac{R_{star}}{a} C_{rec} \left(\sqrt{n} \frac{s_{self-lensing}}{\sigma_{30min}} \right) \quad (16)$$

while the values compared above only include the criteria of edge-on configuration for the binaries, given by

$$\cos_i \leq \cos(89.9) \approx \cos(\pi/2) = 0$$

$$\cos_i \leq \cos(89.9) \approx \cos(\pi/2) = 0 \quad (17)$$

which yields a *searchability index* of ≈ 0.0011 .

⇒ In Masuda & Hotokezaka [15], the 'searchability' constraint includes various criteria such as recovery rate as a function of the signal-to-noise ratio C_{rec} and the eclipse probability R_{star}/a

$$N_{eff} = \frac{R_{star}}{a} C_{rec} \left(\sqrt{n} \frac{s_{self-lensing}}{\sigma_{30min}} \right) \quad (16)$$

while the values compared above only include the criteria of edge-on configuration for the binaries, given by $\cos_i \leq \cos(89.9) \approx \cos(\pi/2) = 0$

$$\cos_i \leq \cos(89.9) \approx \cos(\pi/2) = 0 \quad (17)$$

main cause of the current residual values is the duality of the searchability criteria. I will evaluate the additional constraints and minimize the residuals to confirm that the occurrence rates from COMPAS simulation are reasonable and in line with the occurrence rates expected from TESS by Masuda and Hotokezaka [14]. Then, in the first part of this task, I will search for microlensing events in TESS data with predicted mass and semimajor axis parameters to compare with the COMPAS results. A discrepancy between the predicted and observed populations where observed abundance is higher or a discrepancy of the peak semimajor axis might indicate BH-MS systems formed by capture.

Table 1: Updated quantities from the simulation log file.

Quantity	Pre-MT	Post-MT	Post Last MT
Number of systems	29,000,000	-	-
Number of systems forming MT (via SP STATUS)	17,029,983	-	-
Number of primary mass BHs	2,207,804	2,671,970	-
Number of secondary mass BHs	513,929	2,132	-
Number of unbound binaries	1,851,730	-	-
Number of double compact objects	863	-	-
Number of mergers	0	-	-
Number of BH-NS binaries	0	3,533	-
Number of NS-BH binaries	0	269	-
Number of BH-MS binaries	1,398,490	1,441,991	29,740
Number of MS-BH binaries	0	0	0
Number of systems with semimajor axis < 3.0 AU BH-MS binaries	1,398,149	1,441,991	29,740
Number of systems with semimajor axis < 3.0 AU MS-BH binaries	0	0	-
Number of systems with orbital period < 70 days BH-MS binaries	1,397,834	1,441,624	29,660
Number of systems with orbital period < 70 days MS-BH binaries	0	0	0
Number of systems with orbital period < 30 days BH-MS binaries	-	1,440,658	29,384
Number of systems with orbital period < 30 days MS-BH binaries	-	0	0
Number of systems with semimajor axis < 0.4 AU BH-MS binaries	-	1,440,600	29,380
Number of systems with semimajor axis < 0.4 AU MS-BH binaries	-	0	0
Number of systems with orbital inclination (COSI) < 89.99° BH-MS binaries	1,539	1,656	38
Number of systems with orbital inclination (COSI) < 89.99° MS-BH binaries	0	0	0

2025-05-09

Number of systems with orbital inclination (COSI) < 89.99° MS-BH binaries	0	0	0

results show that among 58.72% of the binaries are undergoing MT events about 0.17% of these systems end up in BH-MS binaries. 99.73% of these BH-MS binaries have orbital periods shorter than 70 days within the observational limits of the Roman. For total population, this corresponds to 0.10%.

As an explanatory case, we choose to work with Starlink constellations.
10 Days Starlink Positions
— Altitude of the of 6412 Starlink satellites with 6-second iteration intervals throughout the night observed from the Rubin Observatory in Cerro Pachón, Chile. The color scale demonstrates the azimuth of the satellite in the sky.

Side Quest

The peak magnitudes of the satellites during each trail event window and the average of these peak magnitudes for each trail event window in arcseconds.

: all starlink events above 30 degrees for each satellite within 24h.

Blue: trail candidates, green conditions plus during outside the day time and reflecting sunlight

Side Quest: Investigating Streak Contamination

The LSST survey is challenged by the increasing number of Sun-reflecting artificial satellites. Here we focus on the Low Earth Orbit (LEO) satellites, which are brighter due to their lower altitudes and contributing as a larger population.
